Abstract

The serious games between humans and AI have only just begun. Evolutionary Game Theory (EGT) models the competitive and cooperative strategies of biological entities. EGT could help predict the potential evolutionary equilibrium of humans and AI. The objective of this work was to examine some of the EGT models relevant to human-AI interaction, evolution, and coevolution. Of thirteen EGT models considered, three were examined: the Hawk-Dove Game, Iterated Prisoner's Dilemma, and the War of Attrition. This selection was based on the widespread acceptance and clear relevance of these models to potential human-AI evolutionary dynamics and coevolutionary trajectories. The Hawk-Dove Game predicts balanced mixed-strategy equilibria based on the costs of conflict. It also shows the potential for balanced coevolution rather than dominance. Iterated Prisoner's Dilemma suggests that repeated interaction may lead to cognitive coevolution. It demonstrates how memory and reciprocity can lead to cooperation. The War of Attrition suggests that competition for resources may result in strategic coevolution, asymmetric equilibria, and conventions on sharing resources. Therefore, EGT may provide a suitable framework to understand and predict the human-AI evolutionary dynamic. However, future research could extend beyond EGT and explore additional frameworks, empirical validation methods, and interdisciplinary perspectives. AI is being shaped by human input and is evolving in response to it. So too, neuroplasticity allows the human brain to grow and evolve in response to stimuli. If humans and AI converge in future, what might be the result of human neuroplasticity combined with an ever-evolving AI? Future research should be mindful of the ethical and cognitive implications of human-AI interaction, evolution, and coevolution.

Keywords: evolutionary game theory, human-AI interaction, human and AI coevolution, neuroplasticity and AI evolution

1 INTRODUCTION

Game Theory focuses on the "game"—a strategic or social setting in which two or more independent decision makers, or players, compete to produce an outcome [1, 2]. This theory can be applied to zero-sum games, which are competitive, and non-zero-sum games, which can be either competitive or non-competitive. An important enhancement of Game Theory is Nash Equilibrium [3], which describes the outcome of adversarial, non-cooperative games. It focuses on the point where the game reaches a state of equilibrium and no player can win an advantage by changing their strategy unilaterally. The main limitation of Game Theory and Nash Equilibrium is the assumption that players in a game are rational, self-interested, and maximize utility.

Prisoner's Dilemma [4, 5] is a well-known illustration of Game Theory and Nash Equilibrium. It shows why two rational players may or may not cooperate, even if cooperation is in their best interest. Nash Equilibrium does not consider players' past behavior [6]. However, past behavior influences future behavior [7] and may be the best predictor of future behavior [8].

Evolutionary Game Theory (EGT) [9-11], an influential offshoot of Game Theory, does not have these limitations. It is not based on the artificial construct of purely rational players whose decisions are underpinned by rationality alone. It describes interactions between living things such as microorganisms, birds and animals in the natural world. It predicts the likely outcome of competitive strategies employed by biological species, within a single generation or over evolutionary timescales. This theory has also been extended to describe the outcome of cooperative strategies [12].

Therefore, EGT is more applicable to the real world than Game Theory. It is being constantly refined and enhanced to analyze an ever broader and more complex set of situations. Based on this theory, Sandholm [13] created a framework for the relationship between the evolutionary dynamics of a population and the rules that individuals within that population use, to learn. Skoulakis et al. [14] described an enhancement in which players compete in a scalable, zero-sum game. The players, the environment, and the game itself evolve over time.

With the advent of AI, particularly advanced Generative AI, the concept of population, evolution, and serious games may extend beyond biological entities alone [15]. There are various flavors of Generative AI—ChatGPT, Claude AI, Bard, Perplexity, and many more, that can be regarded as an AI population. Further, these Generative AI may herald a new era dominated not just by artificial intelligence, but by artificial life [16]. Neuroevolution, an established branch of research on artificial life, aims to evolve—not design—artificial brains [17]. Adami [18] proposes that the process of Darwinian evolution should underpin the production of artificial brains fitted into robots, to create fully sentient machines.

It seems inevitable that there will be numerous types and forms of AI in future, and that they will be far more advanced than Generative AI. As the evolution of the AI population accelerates, it may be useful, and important, to build robust frameworks and models—or adapt existing ones—that can predict human-AI interaction, evolution, and coevolution, over time. EGT, and well-established models based on this theory, may lead the way in developing appropriate and predictive frameworks and tools.

In the modern era, interest in AI began in the 1950s [19-21]. In less than a hundred years, interactions with AI may already be affecting human cognition, both positively and negatively. For example, while AI processes vast amounts of information on digital platforms and helps guide human preferences in activities such as shopping, it may reduce the ability of humans to make decisions on their own [22]. Another example is the use of Global Positioning System (GPS) navigation with AI chatbots in cars and other vehicles, which may have a negative impact on the cognitive processes that create spatial knowledge [23]. AI may also impact human cognition in terms of attention, memory, addiction, and perception, and reinforce novelty-seeking behaviors [22]. Resilience and determination have underpinned human survival and achievement for millennia. The burning question is whether societies will take these attributes forward or trade them for the convenience that AI offers.

AI is an artificial entity created by humans, but it may be evolving in a manner similar to biological entities. Baber [15] elaborated on Kelly's argument [24] that technology is a natural extension of biological evolution—a living force that can extend human potential. Turkle [25] postulates that the use of technologies such as txt, email, and social media change the way humans view themselves and their relationships with others. Turkle argues that technology has become such an extension of the human self that it is a 'phantom limb' when humans are separated from it even briefly. Mijwil and Abttan [26] discuss the possibility of transhumanism in future—the merging of humans on the one hand and AI-powered robots on the other, into cybernetic beings or cyborgs.

Ramsey [27] postulated that humans make decisions by maximizing expected utility. However, this theory of human decision-making behavior is incomplete if not problematic [28-32]. It is more likely that humans make complex decisions based on cognitive and affective processes [33, 34]. As AI evolves, will its decisions be based on a different class of cognition and on different affective processes?

Artificial neural networks (ANN) and AI are based on the current knowledge and understanding of human neural networks [35]. However, the exact structures and processes of human neurons, their connections, and networks are yet to be fully understood [36]. In fact, the brain has the ability to adapt, learn and grow based on experience and external stimuli. This process is known as neuroplasticity [37]. Neuroscientists are now learning more about human neuronal networks and connections by studying ANN structures [38]. Humans and AI are already learning from each other, it seems, with AI and ANN based on human neural networks, and neuroscientists in turn learning from ANN. Litt et al. [39] proposed the Neural Affective Decision Theory. It is based on four principles: decision-making is a cognitive-affective process; it is coordinated by interconnected neurons that interact across various areas of the brain; preferences are formed by different but interacting mechanisms mediated by the chemicals dopamine and serotonin; and decisions and judgements depend on patterns of neural activation based on how information is framed and presented.

In the context of EGT, strategic substitutes and strategic complements are fascinating concepts that may significantly influence interactive decision-making. Strategic substitutes are scenarios where players' decisions offset each other [40]. In evolutionary contexts, strategic substitutes are the foundation of competitive dynamics. On the other hand, strategic complements are scenarios in which the decisions of two or more players mutually reinforce one another [40]. In evolutionary contexts, strategic complements tend to create dynamics where successful strategies spread through populations and positive feedback loops lead to convergent evolution. Strategic complements may also predict stable evolutionary outcomes, known as Evolutionarily Stable Strategy (ESS), which is one of the cornerstones of EGT.

EGT incorporates Game Theory, Darwin's theory of evolution, and the role of heredity and natural selection [41]. It provides a robust theoretical foundation for diverse disciplines, including economics, social sciences, and biology. Importantly, it is also relevant to understanding ecological dynamics and coevolution [42].

1.1 Rationale and Objectives

EGT has been used to predict human behavior in many competitive and cooperative situations [43-47]. It has also been applied to AI behaviors [48, 49]. Therefore, it may form a suitable theoretical basis to explore the nature of serious games that humans and AI play. The objective is to examine some of the relevant EGT models through the lens of human-AI interaction, evolution, and coevolution. The aim is to explore how each model could potentially apply to the serious games between these two entities.

2 METHODS

There are numerous EGT models across a variety of disciplines, including biological processes acting over millions of years, cultural processes acting over generations, and relevant dynamic models [50]. Table 1 lists thirteen established EGT models with a brief description of each, noting that this list is far from exhaustive.

Table 1: A non-exhaustive list of thirteen Evolutionary Game Theory (EGT) models

Number	Evolutionary Game Theory Model	Description
1	Hawk-Dove Game [9]	Conflict over resources, where aggressive (hawk) and passive (dove)
		strategies compete, typically reaching mixed equilibria where both
		strategies coexist in the population.
2	Iterated Prisoner's Dilemma [12, 51]	Repeated interaction between players, where they can either cooperate
		or defect. This model examines the emergence of reciprocity and
		cooperation. Notable strategies include Tit-for-Tat, Win-Stay-Lose-
		Shift, and Zero-Determinant strategies.
3	War of Attrition [10, 52-54]	A contest where competitors persist in costly conflict until one
		withdraws, resulting in an Evolutionarily Stable Strategy (ESS) where
		individuals randomly select persistence times from a probability
		distribution, preventing any one strategy from dominating.
4	Public Goods Games [55]	This models collective action problems, where individuals decide
		whether or not to contribute to a common resource that benefits
		everyone.
5	Replicator Dynamics [56]	A mathematical foundation describing how strategy frequencies
		change over time, based on their relative fitness, formalized through
		differential equations that model selection processes.
6	Indirect Reciprocity [57-59]	Examines how cooperation evolves through reputation mechanisms
		even when direct reciprocity is not possible.
7	Spatial and Network Games [60]	Extensions of other models that incorporate the effects of spatial
		structure or network topology on evolutionary outcomes.

Number	Evolutionary Game Theory Model	Description
8	Ultimatum Game in Evolutionary Context [61]	This studies how fair or unfair offers evolve over time through selection processes.
9	Group Selection [62]	Examines how competition between groups can favor cooperation within groups, even when it is costly to individuals.
10	Adaptive Dynamics [63-65]	Models gradual evolution of continuous traits through small mutations, focusing on long-term evolutionary trajectories.
11	Moran Process [66, 67]	A stochastic model for finite populations that examines fixation probabilities of strategies.
12	Price Equation [68]	A mathematical framework that divides a selection into different components. This model can be used to analyze the evolution of cooperation.
13	Continuous Strategy [56, 69, 70]	Extensions where players can choose from a continuous range of strategies instead of choosing from discrete options.

In the interest of time and resources, a decision was made to examine only three of these models, based on their widespread acceptance and clear relevance to human-AI interaction, evolution, and coevolution. Each of these models was examined from the perspective of human and AI decision-making attributes [71-73]. The models were also examined from psychological and biological perspectives and from the perspective of artificial intelligence:

- The Hawk-Dove Game [9] models aggressive and cooperative strategies based on a paradigm of interaction between hawks and doves. Hawks aggressively pursue resources regardless of cost, while doves share resources or demonstrate strategic displays, but retreat if challenged. The model demonstrates why natural selection often favors limited conflict over potentially destructive escalation of conflict. The game typically results in mixed-strategy equilibria based on the relative costs of aggression versus cooperation, rather than pure strategic dominance.
- Iterated Prisoner's Dilemma [12, 51] is an extension of classic Prisoner's Dilemma [4, 5]. It allows players to interact repeatedly over multiple rounds of the game, remember previous choices, and adjust strategies accordingly. Each player must repeatedly decide whether to cooperate or defect, with payoffs determined by a combination of the choices made by both the players. This repetition enables the emergence of reciprocity, reputation, and conditional strategies such as tit-for-tat. The model demonstrates how cooperation can emerge through repeated interaction, even when defection may be rational in single encounters.
- The War of Attrition was described in 1974 [10] and expanded later [52-54]. It models competitive scenarios where two contestants vie for a resource through persistent displays or confrontation, until one participant withdraws. Over time, costs accumulate for both competitors. The competition is based on endurance and creates a strategic balance. The decision to withdraw depends on a player's assessment of a resource's value and their tolerance for the costs.

3 RESULTS

The analysis of the three EGT models revealed distinct patterns that can be applied to human-AI interaction.

- The Hawk-Dove Game suggests that mixed-strategy equilibria will likely emerge between humans and AI, with
 neither cooperation nor competition dominating. Instead, a dynamic balance is likely, based on the costs of conflict.
 When AI systems adopt aggressive "hawk" strategies, they may trigger defensive regulatory responses, while mutual
 "dove" strategies enable cooperative coevolution.
- Iterated Prisoner's Dilemma indicates that repeated interaction between humans and AI may create cognitive
 coevolution. This could lead to cooperative equilibrium, competitive escalation, or convergence based on memory
 capacity and reward structures.
- The War of Attrition suggests that competition for resources may drive strategic coevolution, where each entity's
 persistence threshold influences the timing of withdrawal. This could result in conventions for resource sharing,
 optimal contest durations, or asymmetric equilibria, depending on cost tolerance and the value assigned to a resource.

4 DISCUSSION

4.1 Hawk-Dove Game

Pioneered by Smith and Price [9], the Hawk-Dove Game may offer profound insights into human-AI coevolution. The model examines competitive scenarios in which aggressive (hawk) and cooperative (dove) strategies co-exist, resulting in restrained conflict and evolutionarily stable outcomes, despite more aggressive alternatives.

The Hawk-Dove Game demonstrates why natural selection may favor limited conflict over escalated fighting, explaining why ritualized contests are more common in nature than fights to the death. In the context of human-AI interaction, this model illuminates a strategic landscape where both entities may adopt cooperative approaches that reduce the costs of conflict, instead of more aggressive, resource-hungry strategies. Animals evolve to favor limited conflict, or displays of conflict, instead of lethal combat. Similarly, humans and AI systems may evolve to balance competition with cooperation.

The Hawk-Dove Game suggests that when AI systems adopt "hawk" strategies that maximize their objectives without constraint, they may trigger defensive "hawk" responses from humans through regulation or disconnection. Conversely, when both adopt "dove" strategies, cooperative coevolution becomes possible. Therefore, this model points to the likelihood of mixed-strategy equilibria emerging in human-AI coevolution, where neither pure cooperation nor pure competition dominates. Instead, a dynamic balance may develop, based on the relative costs of conflict versus cooperation.

In animal studies, Hardy and Mesterton-Gibbons demonstrated that this model extends to triadic interactions, alliances, respect for territory, and signaling behaviors. Similarly, in future, human-AI coevolution may result in coalition formation, mutual respect for domains, and status displays that shape the boundaries of interaction. Such Evolutionarily Stable Strategies (ESS) between humans and AI may result in neither complete technological dominance nor rejection. Instead, a complex coevolutionary dance of strategic adaptations may develop, where each entity influences the trajectory of the other's evolution.

4.2 Iterated Prisoner's Dilemma

Iterated Prisoner's Dilemma [12, 51], a model that stems from EGT, is an important variation of Prisoner's Dilemma [4, 5]. In this model, two players select mutual strategies repeatedly, and remember their past behaviors. This is not only applicable to human interactions, but also to interactions between biological species that are engaged in endless games, in nature. Iterated Prisoner's Dilemma has been applied to social sciences such as sociology, economics, and politics, as well as biological sciences like evolutionary biology [74, 75].

This model is not only relevant to interactions between different biological species, but also to interactions between AI. DeepMind Technologies, a subsidiary of Google's parent company Alphabet Inc., applied Prisoner's Dilemma and Iterated Prisoner's Dilemma to AI [76], with interesting results. When two AI players were pitted against each other, they modified their behavior to cooperate or compete, depending on the context [76]. These findings indicate that AI players apply complex attributes to arrive at strategic and context-dependent decisions. Humans, too, apply complex attributes to make effective decisions: for instance, they may deploy both rationality and intuition in decision-making [73, 77]. In evolutionary terms, repeated interaction between humans and AI may create cognitive coevolution, with each entity's decisions influencing the other's adaptive responses.

4.3 War of Attrition

The War of Attrition [10, 52-54] is an EGT model in which two players compete for a resource by displaying, waiting, or fighting, with the contest ending when one player withdraws. The longer the duration of the contest, the greater the cost; therefore, this is a war of endurance. This is not only applicable to human conflicts, but also applicable to competitions between players like insects and territorial animals engaged in costly signaling, in nature [78].

This model is an important variation of the Hawk-Dove Game [10]. It has been applied to disciplines such as economics, political science, and conflict studies, as well as biological sciences like behavioral ecology [79]. DeepMind Technologies applied War of Attrition principles to AI resource allocation [80]. When multiple AI agents competed for limited computational resources, they developed sophisticated withdrawal strategies based on assessments of cost and predictions of opponent behavior [80].

This model is relevant to competitions between different biological species as well as resource conflicts between AI systems. Therefore, it could be applied to competitive scenarios between biological and non-biological entities as well—humans and AI, for instance. In evolutionary terms, repeated resource competitions between humans and AI may create strategic coevolution, with each entity's persistence threshold influencing the timing of the other's withdrawal.

The War of Attrition model may be an appropriate basis for the study of competition for resources between humans and AI. Humans apply complex attributes to optimize competitive outcomes, including competition for resources. When they make decisions under uncertainty, the results vary; for example, the social dilemmas of consuming resources equitably during the COVID-19 pandemic [81] or in the era of climate change [82]. Similarly, DeepMind's findings show that AI is capable of nuanced responses when competing for resources. In a War of Attrition, its withdrawal threshold is based on the value of a resource and the context of the competition [80]. Depending on the cost tolerance of each of these entities, and the value they each assign to a resource, the coevolution of humans and AI may result in conventions or agreements on sharing resources, optimal durations for contests, and/or asymmetric equilibria.

4.4 Assumptions and Limitations

This examination is limited by its selective focus on three EGT models from a broader theoretical landscape. It also assumes that current AI capabilities will scale predictably without major paradigm shifts. In addition, cultural and ethical dimensions of human-AI coevolution receive limited attention. Future research could address these limitations through a more comprehensive theoretical exploration across disciplines and through empirical studies of human-AI interaction.

5 CONCLUSIONS

This examination of three established EGT models through the lens of human-AI interaction, evolution, and coevolution. These models—the Hawk-Dove Game, Iterated Prisoner's Dilemma, and the War of Attrition—may offer valuable insights into conceptualizing and potentially predicting the complex dynamics emerging between humans and AI. Both entities are evolving, as are the environments in which they play—and the game itself.

The Hawk-Dove Game illustrates how mixed-strategy equilibria between cooperation and competition might develop, potentially leading to a balanced coevolutionary relationship rather than dominance by either entity. The Iterated Prisoner's Dilemma highlights how memory, reciprocity, and repeated interaction could foster cooperative behaviors between humans and AI, with each influencing the other's adaptive responses. The War of Attrition model provides insights into how resource competition might drive strategic coevolution, based on persistence thresholds and value assessments.

Understanding evolutionary dynamics may be crucial to guiding the relationship between humans and increasingly sophisticated AI. While this is a limited theoretical exploration, it suggests that EGT may provide a suitable theoretical basis to examine the evolutionary dynamic between these two entities. The initial exploration of three EGT models indicates that human-AI evolution and coevolution may well favor cooperative equilibrium over competitive escalation or the dominance of a single entity.

The serious games between humans and AI have only just begun. While EGT holds promise as a suitable framework, future research could extend beyond it and explore additional approaches, empirical validation methods, and interdisciplinary perspectives. AI is being shaped by human input and is evolving in response to it. In tandem, the neuroplasticity of the human brain allows it to grow and evolve in response to life's experiences. How will AI influence human evolution based on this phenomenon? If humans and AI converge in future, what might be the result of human neuroplasticity combined with an everevolving AI? Future research should be mindful of the ethical and cognitive implications of human-AI interaction, evolution, and coevolution.
